

Post your initial response by Friday Sept 18.

Peer Response Instructions (Due Sunday by 11:59 PM): Reply to at least two classmates using 2–3 sentences per response. Provide meaningful feedback by highlighting a key strength in their response or gently explaining any concepts they could clarify.

Note: Short comments like "Great post!" or "I agree!" will not receive credit.

Apologies on the delay, finish training and had to travel during these last few days.

1. bar graphs Vs histograms. A bar graph is best used when comparing categories, such as the number of people in different age groups or the number of students for different majors. A histogram, on the other hand, is used to show the distribution of numerical data, such as exam scores, salaries, or ages

2. I experimented with `hist()`, which creates a histogram to visualize data. Generating a histogram using that code and pairing it with existing data (count for example), can show the distribution in a dataset. This makes it easier to identify where most values fall and whether the data is spread out or clustered around certain values.

3. Getting back into it, it took me a minute to remember how the program works and the coding that goes into it to make it function. I was prone to errors and making a small mistake, such as misspelling or forgetting a parenthesis, prevented the code from running correctly. Double-checking the code before running it or running it to see where the error occur helped me adjust and learned what I needed to catch before continuing.
